Trends in pre-military sexually transmitted infections and associated risk behaviours in Canadian Armed Forces recruits

Heather McCuaig Edge¹*

Abstract

Background: Sexually transmitted infections (STIs) have historically been problematic for militaries. Recent reports indicating that rates of STIs among young male Canadian Armed Forces (CAF) members are higher than civilians prompted a need to better understand CAF members’ reported rates of STIs and their behavioural risk factors for STIs. This study examined the prevalence of self-reported pre-military sexual behaviours (i.e. number of sexual partners and frequency of condom use) and history of a STI diagnosis among CAF recruits attending basic military training using data collected from the Recruit Health Questionnaire.

Methods: Data came from 50,603 recruits who participated in the survey between 2003 and 2018 (84.9% male, 78.6% Non-Commissioned Member candidates, 64.9% aged between 17 and 24 years).

Results: Among sexually active recruits, the proportions who had more than one sexual partner in the previous year increased from 30.5% in 2003 (95% CI, 27.8–33.4) to 35.5% in 2018 (95% CI, 34.0–37.0). Of recruits who were not in an exclusive relationship at the time, the proportions who reported always using a condom decreased from 50.8% in 2003 (95% CI, 46.4–55.1) to 40.2% in 2018 (95% CI, 38.3–42.2). Overall, 5.5% (95% CI, 5.3–5.7) reported ever having received a STI diagnosis. Demographic differences by age and sex were also found.

Conclusion: These observations provide an indication of the baseline, pre-enlistment STI risk behaviours, and STI history among CAF recruits, and may provide insight into avenues for targeted interventions and health promotion programming, such as education and screening initiatives.

Keywords: sexually transmitted infections, Canadian Armed Forces, military recruits, risk behaviours, condom use, number of sexual partners

Introduction

Sexually transmitted infections (STIs) have historically been problematic for militaries (1,2). For example, reported rates of STIs have been much higher in the United States (US) military population compared with the civilian population (3–5). Recent comparisons between the Canadian general population (CGP) and Canadian Armed Forces (CAF) personnel revealed that while rates of STIs were the same as or lower than civilians in most demographic groups, the rates of STIs among young (i.e. younger than 30 years) male CAF members were almost double those of their civilian counterparts (6). A qualitative study revealed that CAF personnel and healthcare providers alike perceived STIs as a problem within CAF, and many indicated that STIs were similarly, or even more, problematic for CAF than for the CGP (7).

The Public Health Agency of Canada has identified behavioural risk factors associated with STIs; including sexual activity in youth younger than 25 years, new or more than two sexual partners in the previous year, unprotected sex, alcohol or substance use and a history of a STI, among others (8). Military members may be at elevated risk for acquiring STIs given the younger age of the majority of personnel, frequent and extended time spent away
from home for training or operations, deployments to areas with higher rates of STIs, or elevated rates of risk-taking attitudes and behaviours associated with STIs (9–11). Self-reported STI risk behaviours among serving CAF members indicated that almost 21% reported having had two or more sexual partners in the previous 12 months, and of those, only 22% reported always using a condom, while approximately 18% reported never using a condom (12).

Determining the baseline prevalence and demographic profiles of STI risk behaviours and STI history among new recruits can inform education, screening and intervention practices at the beginning of the military career. Thus, this study examined the prevalence of STI risk behaviours (i.e. number of sexual partners and frequency of condom use) and self-reported pre-military history of a STI diagnosis among CAF recruits attending basic military training (BMT).

Methods

Data for this study were collected between July 2003 and December 2018 using the Recruit Health Questionnaire (RHQ), administered during the first few weeks of BMT at the Canadian Forces Leadership and Recruit School in St-Jean-sur-Richelieu, Quebec. All Regular Force Non-Commissioned Member (NCM) and Officer candidates (hereafter collectively referred to as “recruits”) enrolled in BMT were invited to complete the RHQ—a long-term, ongoing surveillance study that provides baseline health and lifestyle information about recruits. The RHQ is a voluntary survey that recruits provide written consent to participate in. Participants’ data is linked via service number to health data collected later in their career; thus, data are confidential, not anonymous. Approximately 75% of recruits completed the RHQ. The RHQ study protocol was approved by the Defence Research and Development Canada Human Research Ethics Committee.

The RHQ includes items assessing number of sexual partners in the previous year, frequency of condom use and STI history. Number of sexual partners was assessed with the question “How many different sexual partners have you had in the past 12 months?” with response options of “none,” “one partner,” “two partners,” “three partners” or “four or more”. Frequency of condom use was assessed with the question, “If you were not in an exclusive relationship at the time, how often did you use a condom in the past 12 months?” with response options of “always,” “usually,” “occasionally,” “never” and “not applicable”. The proportion of respondents with a previous STI diagnosis were estimated based on “yes/no” responses to the question, “Have you ever been told by a doctor or nurse that you had a sexually transmitted infection—like chlamydia, gonorrhea, genital herpes, or syphilis?” The procedure of administration and questions related to sexual behaviours and STI history has not changed over the 16-year period.

The data about sexual behaviours and STI history are self-reported and are, thus, subject to recall and social desirability biases, which may result in under or over-reporting (13). As noted elsewhere (14), while the impact of social desirability on self-reports of sexual behaviours is difficult to quantify, studies have confirmed the general reliability of responses.

Descriptive analysis of crude proportions along with 95% CIs was examined for each cohort year. Sequential logistic regressions controlling for age and sex were conducted to identify linear and non-linear (i.e. quadratic or cubic) trends over time, with cohort year (or its squared or cubed value) entered as a continuous variable. A trend was detected if the addition of cohort year (or its squared or cubic values) to the model significantly improved the model fit, as indicated by a significant chi-square. Difference tests between cohort years were conducted using z-tests of proportions, while chi-square analyses were conducted to detect demographic differences.

Results

Data were available for 50,603 cases from recruits who participated in the RHQ between July 2003 and December 2018. Respondents were mostly male (84.9%), NCM candidates (78.6%), primarily English-speaking (72.7%) and between 17 and 24 years old when they completed the RHQ (64.9%; M=24.0; SD=5.9).

Trends, 2003–2018

Among sexually active recruits, the proportions who had two or more sexual partners in the previous year increased from 30.5% overall in 2003 (95% CI, 27.8–33.4) to 35.5% overall in 2018 (95% CI, 34.0–37.0; p<0.01; Figure 1). Significant trends, controlling for age and sex, indicated that the number of sexual partners reported by recruits in the previous year have fluctuated between 2003 and 2018 ($\chi^2 (5) = 1,344.28; p<0.001$).

Of recruits who were not in an exclusive relationship at the time, the proportion who reported always using a condom decreased from 50.8% in 2003 (95% CI, 46.4–55.1) to 40.2% in 2018 (95% CI, 38.3–42.2; p<0.001; data not shown). As depicted in Figure 2, the proportion who reported never using a condom increased from 16.5% in 2003 (95% CI, 13.5–20.0) to 25.7% in 2018 (95% CI, 24.0–27.5; p<0.001). Respondents who selected “not applicable” were excluded from these analyses, resulting in a reduced n=27,783 for this STI risk behaviour. Significant trends controlling for age and sex were found, indicating that rates of condom use reported by recruits during the previous year have varied significantly over the 16-year period ($\chi^2 (5) = 400.70; p<0.001$).

Overall, 5.5% (95% CI, 5.3–5.7) of recruits reported ever having received a STI diagnosis (Figure 3). These proportions were not significantly different for the 2003 or 2018 recruit cohorts.
There was a significant trend found in the rates of recruits having reported ever having had a STI diagnosis ($\chi^2 (5)$=445.18; $p<0.001$) after controlling for age and sex, indicating that the rates of reported STI diagnoses varied over the 16-year period.

Demographic differences

Pooling responses over the 16-year period, demographic differences by sex and age were also found for number of sexual partners, condom use and STI history. As depicted in Figure 4, more male than female recruits reported having two or more sexual partners in the previous year ($\chi^2 (2)$=716.75; $p<0.001$), while more female than male recruits reported a previous STI diagnosis ($\chi^2 (1)$=43.44; $p<0.001$). Of recruits who were not in an exclusive relationship at the time, more female than male recruits reported always using a condom (data not shown; $\chi^2 (2)$=84.93; $p<0.001$); however, there were no differences in the proportions of male and female recruits who reported never using a condom.

As depicted in Figure 5, the proportions of reports of having two or more sexual partners in the previous year significantly differed for each age group ($\chi^2 (6)$=3,183.48; $p<0.001$), with the highest proportion among recruits aged 20 to 24 years. Recruits aged 30 or older who were not in an exclusive relationship had the highest proportion of reports that they never used a condom,
with the proportions being significantly lower in each descending age group ($\chi^2 (6)=365.01; p<0.001$). There were proportionally more recruits aged 25 or older who reported a history of an STI diagnosis than younger recruits ($\chi^2 (3)=512.67; p<0.001$), with the youngest group of recruits (i.e. those aged 17 to 19 years) reporting the lowest proportion of STI diagnosis history.

Figure 5: Sexually transmitted infections history and associated risk behaviours by age group in Canadian Armed Forces recruits

Differences in the number of sexual partners between men and women were consistent with findings that men tend to report having more sexual partners than women (14,21,22). This difference may be due to socialization, gender roles or sociocultural norms surrounding sexual behaviours and the reporting thereof (26). In line with findings from the CGP (21,22), the proportion of recruits reporting multiple partners was lower in the older age groups, possibly due to increased likelihood of older recruits being in longer term, monogamous relationships. The largest proportion of recruits reporting multiple partners was among the 20 to 24-year old group, which is the age group with the highest rates of gonorrhea (17) and chlamydia (16) and the third highest rates of infectious syphilis in the CGP in 2015 (15).

Consistent with findings from the CGP that have found that regular condom use declines with age (14,20,23), a higher proportion of older recruits who were not in an exclusive relationship at the time reported never using a condom, compared with younger recruits. This could be due to the increased use of other contraceptive methods for preventing pregnancy with increased age (21); however, these methods do not prevent STIs.

Findings from recruits are consistent with the rates and behaviours found in the CGP; this is unsurprising since recruits were drawn from the CGP and had not yet begun their military careers when the RHQ was administered. The importance of this research for CAF in its efforts to prevent STIs are highlighted by the observed increasing rates of STI risk behaviours, the higher STI rates and risk among military members (3–6,9,27) and perceptions of STIs as a problem for CAF (7). These efforts may be especially important for recruits, who have not yet experienced some of the military situations that may place military personnel at increased risk for acquiring STIs, such as deployments (9,11), or having higher levels of risk propensity (28). While the risk for STIs may be elevated for military members, CAF also presents an opportunity for members to more easily access health care for primary and secondary prevention and health promotion programming. Other militaries have implemented programs that have reduced STI rates, such as in US recruit training centers, and have proven effective at increasing STI knowledge and perceived norms for safe sex (29–33). These programs included mass screening and programming that included presentations and activities to educate about the transmission, symptoms and prevention of STIs, or emphasized adaptive decision-making skills and communication strategies. Other programs aimed at the general population using digital interventions, online programs and social media have been effective at increasing condom use, knowledge and perceived norms surrounding safe sex, especially among younger individuals (34–36). Similar programming and interventions could be implemented in CAF’s BMT program or in other routine training or health promotion activities throughout the military career.

### Discussion

Observations from the RHQ concerning the number of sexual partners, frequency of condom use and STI history, suggest that the majority of recruits were not engaging in risky sexual behaviours. However, at least a third of recruits reported having had two or more sexual partners in the year prior to starting BMT. More recently, among those who were not in an exclusive relationship at the time, a quarter of recruits reported never using a condom. From 2003 to 2018, the proportions of recruits reporting multiple sexual partners and never wearing a condom increased. These patterns in STI risk behaviours mirror the recent increases in rates of STIs reported in the general population in Canada (15–17) and in other high-income countries (18,19), and are also consistent with increased risky sexual behaviours among adolescents and adults in the CGP (14,20,22).

While reports of recruits having had a STI diagnosis prior to BMT have remained relatively low, consistently more female than male recruits reported a history of STI diagnosis. This is unsurprising given that, for certain STIs (e.g. chlamydia), women tend to have higher rates of infection than men (16) and tend to be screened and/or seek health care more regularly, and would, therefore, be more likely to have been diagnosed than men (23–25). Moreover, because of their physiology, women are more susceptible than men to acquire STIs (24).
Strengths and limitations
This surveillance report, based on observational data, presents a baseline indication of pre-enlistment STI risk behaviours and STI history among recruits. It provides trend information for 16 years of recruit cohorts, and describes demographic differences in reports of STI history, number of sexual partners in the previous 12 months and frequency of condom use. These findings underscore the rising trends in risky behaviours associated with acquiring STIs in both the CGP and in CAF recruits, as well as provide insight into demographic information about groups of individuals at particular risk for STIs. These data could inform the development of screening tools to identify segments of the recruit population that might benefit from targeted interventions and health promotion programming.

This study and the RHQ are not without limitations. The RHQ data were self-reported; a technique which is prone to social desirability bias, recall bias and subjectivity (13,37). In addition, there was no way of assessing the accuracy of responses. Further, we had single item measures asking about sensitive topics. As such, some recruits may have been reluctant to disclose personal information about their sexual history and sexual behaviours, which may have resulted in under-reporting. The requirement for an individual to be in an “exclusive relationship” in the question about frequency of condom use may have resulted in the exclusion of individuals who had been in serially monogamous relationships. These individuals may not have responded, as they considered themselves to be in an “exclusive relationship”, yet the nature of these relationships may expose them to a significant number of sexual partners in a short period of time. Moreover, the current RHQ does not consider sexual identity or sexual preference, which may impact risk behaviours for STIs and intervention strategies. Future research on STI risk behaviours with CAF members should take sexual preference into consideration. Finally, the RHQ is voluntary, so results are based on the subset of recruits who chose to respond rather than the whole population of recruits who trained during this period. Although the overall response rate was high (75.6%), there may be demographic differences between respondents and non-respondents.

Conclusion
Since 2003, risk behaviours for acquiring STIs have increased among recruits, but these rates are consistent with similar increases observed in CGP. Findings from this study provide baseline information about sexual risk behaviours for STIs among CAF population, and a demographic profile of those at higher risk for STIs. These findings may provide insight, especially for CAF, into avenues for targeted interventions and health promotion programming, such as education, primary and secondary prevention and screening initiatives.
