Abstract

The identification of risk factors for falls in longitudinal studies becomes difficult because of exposures that change during the follow-up and also because individual subjects may experience an event more than once. These issues have been neglected and improper statistical techniques have been used. The typical approaches have been to report the proportion of fallers or the time to first fall. Both avoid the underlying assumption of independence between events and discard pertinent data. We review the existing methods and propose a Cox hazards extension. We exemplify it in the study of potential risk factors associated with all falls in 959 seniors. Finally, we compare the results of the proposed Wei, Lin, & Weissfeld (WLW) method with those of several other techniques. Stable exposure variables measured at baseline and updated time-varying exposures include socio-demographic characteristics, BMI, nutritional risk, alcohol consumption, home hazards, gait and balance, and medications. Results demonstrate that the usual methods of analyzing risk factors for falling are inappropriate, as they produce considerable biases relative to the WLW model using time-dependent covariates. Results also show that modeling for first events may be inefficient, given that the risk of occurrence varies between falls.

Key words: *Accidental falls, Cox model, elderly, environmental hazards, negative binomial distribution, hazards model, regression analysis, survival analysis, logistic models*

Introduction

Falls are common, recurrent problems with serious consequences for elderly people and the health care system.[1] Evidence of fall-risk factors has generally been identified by prospective observational designs. These studies may suffer from problems similar to those found in cohort studies of other issues, such as loss to follow-up and variable follow-up time. The identification of fall-risk factors deals with additional problems such as exposure changes during follow-up and recurrent events in the same person. These issues have been neglected and inefficient statistical techniques have been used. As a result, this may have distorted the magnitude in estimates of particular predictors or produced misleading results. Moreover, this may have missed questions of great clinical relevance.[2-5]

More than 15 years ago, Cumming, Kelsey, and Nevitt[6] advised that more attention be paid to repeated measures regarding both risk factors and rates for all falls. Despite this, few researchers have challenged the design of their studies and the analysis of their data. Rather, they seem to have been adversely affected, circumventing the methodological complications by discarding much relevant information.

The aim of the present paper is to raise the awareness of researchers about some epidemiological and statistical considerations. We review the statistical background of methods of fall studies, introduce the philosophical issues of time-dependent covariates and multiple events, and discuss the existing statistical techniques which deal with them. We propose an extension of the Cox proportional hazards traditional model and use it in the identification of potential risk factors associated with all falls in elderly people living at home. Finally, we compare the different results obtained by various statistical methods.

Statistical background of methods of fall studies

A variety of strategies has been used to study the risk factors for recurrent falls. Their analysis is complicated by the within-subject correlation. In other words, the occurrence of an event acts on the risk of the next one. Failure to account for dependence in the data leads to the usual estimator of variance being underestimated. This produces confidence

intervals that are too narrow and a test of significance too liberal (i.e. rejects the null hypothesis too often).[3,5,7]

A summary of some of the discussed methods is provided in Figure 1. A simplistic approach to such problems involves reporting the proportion of fallers (subjects who fall at least once over an arbitrarily defined period) or the time to a first fall.[8] Both possibilities avoid the underlying assumption of independent association between multiple events. However, the use of all available data for each individual could be more efficient.[4,8,9] The author of a key paper has argued that the incidence rate for falls was a public health priority[6], particularly for less robust elderly people.[10] The challenge in analysing all falls arises because some elderly are more prone to recurrences than others; hence, they run a higher risk of fall-related injury as opposed to those who fall only once. The choice of outcome, according to whether the focus is on fallers or on the rate of falls, could also affect the conclusion; i.e., knowing whether a particular exposure constitutes a risk factor. Stable over-time factors are more likely to be related to the state of "being a faller" than exposures that vary over time.[6]

Alternatives have been proposed for dealing with multiple events. Among these are the negative binomial regression, some extensions to the Cox proportional hazards model, and a modified logistic regression. The dependent variable in the negative binomial regression is the individual event rate adjusted for the follow-up time i.e., the number of falls for a person divided by their specific follow-up time (Figure 1).[4,11] Since the negative binomial distribution has one more parameter than the Poisson, it naturally accommodates for over-dispersion (i.e., the variance typically exceeds the mean).[8] Therefore, this approach is robust for dependent structure data, and suitable for frequent and recurrent events.

One problem using event rates is that the likelihood of event occurrence must be assumed to be constant through time within one participant. A critical example could be to consider the equivalent event rates for three participants, each of whom is observed over three years and suffers three falls. One has fallen once each year, another three times in the first year, and the last three times in the third year. The outcome variable ignores the time of occurrence of these events.[8] Thus, a negative binomial modeling event rates may not be the method of choice when the value of important covariates or the likelihood of event occurrence changes with the passing of time.[3] Greater efficiency and accuracy can be obtained by modelling the lengths of inter-episode intervals via time-to-event techniques.[9] Rather than focusing on the numbers of cases, the time-to-event approach considers the time between falls. If the incidence rate is high, the intervals between events will be short, and vice versa.[3]

In addition, measured risk factors of which we want to evaluate the effects are usually only fixed variables, defined at the initial examination.[2] They refer to the intrinsic characteristics of the subjects (e.g., the sex), the past exposures (e.g., prior falls) or exposures present at baseline (e.g., use of medication). Exposures that occur after the starting point or vary over time for an individual are not taken into account. Examples, which can potentially cause falls through short-term exposure preceding the event, include environmental hazards, alcohol consumption, and use of medication. A great advantage of the time-to-event approach is its ability to handle time-dependent covariates.[3]

The hazards models include the counting process of Andersen & Gill[16] (hereafter referred to as AG), the conditional model of Prentice, Williams, & Peterson[17] (PWP), and the marginal model of Wei, Lin, & Weissfeld[18] (WLW). None of these approaches explicitly models the dependence structure between failure times. Instead, robust estimates of variance are used to account for correlated observations within subjects; i.e., the so-called «variance-corrected» hazards models.[12-15]

The distinction of the hazards methods can be seen in terms of who is in the risk-set at each failure.[15,19] The AG rests on the strong assumption that the risk of an event for a given subject is unaffected by any earlier events, unless a term that captures such dependence (i.e., number of previous falls) is included as a time-dependent covariate.[3,7] In other words, the data for each subject with multiple events could be described as data for multiple subjects, where each has delayed entry and is followed until the next event (Figure 1). This model ignores the order of the events; i.e., all falls are indistinguishable, leaving each subject to be "at risk" for an event as long as the subject is still under observation at the time the event occurs.[3,7,8,13-15,19]

The PWP is based on the idea that a subject is not technically at risk for a later event until all previous events have been experienced. This is accomplished by stratifying data by event order. Accordingly, the risk-set at time t for the kth event is limited to those subjects under study at t who have already experienced k-1 events (not exemplified in Figure 1).[13-15,19] However, Robertson[20] has argued that the conditional assumption of the order of events does not hold for falls. As an illustration of her argument (personal communication), let us speculate that a person has slipped on water on the kitchen floor without injury and, at another time, has fallen on the pavement outside. This has resulted in a hip fracture. The person is at risk for both these falls from the beginning of the study period; i.e., the time at risk for the second fall on the pavement does not start only after the first fall in the kitchen has occurred.

The risk-set of the WLW marginal approach includes all patients under observation who have not yet experienced the kth event. The time for each event starts at the beginning of follow-up time for each subject. Furthermore, each subject is considered to be at risk for all events, regardless of how many events each subject has actually experienced. The WLW does not impose any dependence structure among the related failure times. Thus, it ignores the ordering of events but takes into account previous events by situating each failure in an independent stratum (Figure 1).[4,7,8,13-15,19]

The logistic regression analysis is the most commonly used method in epidemiological

research. D'Agostino *et al.*[21] showed that a so-called pooled logistic regression is identical to the time-dependent covariate Cox regression. This is what makes the technique attractive to evaluate the relationship of risk factors to disease development. O'Loughlin[22] applied such an approach to the study of falls. The theoretical basis for the use of this logistic regression variant is well established when the intervals between measurements of risk factors are short, the probability of an event within an interval small, and the intercept for the pooled logistic constant across intervals.[21] The underlying statistical requirements and the data setup for the pooled logistic regression are very close to those defined for the AG. Each of the follow-up intervals for a single subject is assumed to represent intervals from different subjects. The method pools the subjects at risk and the events developed in each interval. The follow-up interview number is included as a categorical variable to test this assumption. Similarly, the dependence between multiple falls within the same individual is accounted for by considering the occurrence of previous falls as a predictor variable.[23]

However, the way in which the interval observations are set up, as well as the outcome variable of interest, differs in both methods. The AG builds the intervals according to the precise dates of events. For example, the first interval will cover the time span from entry into the study until the time of the event, and the following interval spans the time from the first event to the next one, and so on (Figure 1).[15] In contrast, the logistic regression uses stable time points fixed by the researcher. For example, an exam could be performed at the same date each month to up-date risk factors and to gather information on falls that occurred in the interval of observation (not exemplified in Figure 1).[22,23] The analysis above is, in essence, an investigation of fallers versus non-fallers in successive short intervals.[22] Even if, taken as a whole, the analysis allows for more than one outcome to occur per subject, less appreciated is the fact that it

FIGURE 1
Schematic representation of statistical models for the study of risk factors for falls
(Modified from a figure published by Robertson, Campbell and Herbison[8])

Hypothetical subject with follow-up of 12 days, falls on day 5 and 8. Let (0) represent no fall and (1) a fall, x_i a risk factor of subject i measured at time t, and k_i its number of falls. Then the baseline hazard is illustrated by $\lambda_0(t)$, the hazard for a fall for the ith subject by λ_i and the hazard of the kth fall for this subject by λ_{ik}. Person-time, pt_i is length of time at risk for subject i, $\beta'x$ denotes the effect size of factor x, p is the probability of event in exposed, e, and unexposed, u, subjects.

Standard Cox regression. One data record covers entry until the 1st fall and discards any information past that point. Total follow-up time is assigned to individual that never fell. The dependent variable is time to first fall.
$$\log\left(\frac{\lambda_i(t)}{\lambda_0(t)}\right) = \beta'x_i(t)$$

Andersen-Gill Cox regression. Three records cover entry until the 1st fall, from the 1st until 2nd fall, from the last fall to the end of follow-up, the latter period being fall-free. The dependent variable is time to each fall.
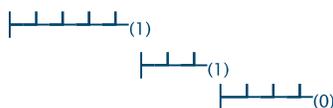

$$\log\left(\frac{\lambda_i(t\mid x_i(t))}{\lambda_0(t)}\right) = \beta'x_i(t)$$

Marginal Wei, Lin & Weissfeld regression. Three records. Each fall as well as the final fall-free period are treated in an independent stratum and time measured from entry. The dependent variable is time to each fall.
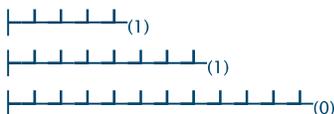

$$\log\left(\frac{\lambda_{ik}(t\mid x_{ik}(t))}{\lambda_{0k}(t)}\right) = \beta_k x_{ik}(t)$$

Negative binomial regression. One record covers entry until the end of follow-up and includes simply the total number of falls and follow-up time per subject. The dependent variable is number of falls.

$$\log\left(\frac{k_i}{pt_i}\right) = \beta_0 + \beta'x_i$$

Logistic regression. One data record, which does not account for follow-up time and ignores multiple falls by subject. The binary dependent variable is status of faller.

$$\log\left(\frac{\dfrac{p_e}{1-p_e}}{\dfrac{p_u}{1-p_u}}\right) = \beta'x_i$$

drops all additional falls that may occur in each particular interval. It seems obvious that if three falls per month are considered equivalent to one fall for the same period, the information translating the intensity of short-term phenomena is lost.

The choice of one of these models must be made starting from *a priori* ideas on the types of relationships which exist between the covariates and the risk of falling. In negative binomial regression, AG, and pooled logistic regression, no distinction is made between the various events that succeed one another. This restricts the baseline hazard and the regression coefficients do not vary according to the rank of recurrence. A history of previous falls is strongly recognized as a predictor of subsequent falls.[10,23] Intuitively, we would expect a first fall to differ from the aetiology of the subsequent falls. The predictors for one fall that can occur by accident might be different from those for recurrent falls that can be associated with one's health condition.[24,25] Hence, researchers and practitioners may be interested in knowing not only the overall covariate effects on the risk of all failures, but also the specific effects of independent variables for the first, second, or subsequent events. The binomial regression, AG, and pooled logistic regression, contrary to the WLW, provide no insights to answer such questions. In accordance with the structure of the data to be analyzed and the research question to be answered, the WLW is expected to be a naturally more appropriate method for studying the risk factors of falls.

Methods

Subjects and procedures

Subjects were volunteers recruited bet-ween March 2002 and July 2005 to form an open cohort that included community-dwelling persons, aged 65 years and over and receiving home-care services. People who could speak neither French nor English, those not able to walk more than six meters, and those with reduced communication and cognition were

excluded. All subjects gave informed consent. The study was approved by the authorities of each participating centre.

This study is a part of a research project on the evaluation of a multifaceted preventive intervention.[26] Participants were visited at home, at entry and every six months, by a trained physical rehabilitation therapist in order to ascertain information about potential risk factors. A fall was defined as an event resulting in the subject inadvertently coming to rest on the ground, floor or other lower level (e.g., stairs). Excluded were sports-related falls.[23] Subjects were asked about falls in the three months preceding the initial interview and were monitored for new falls by use of a daily completed calendar and monthly phone calls.

Material and social forms of an ecological deprivation index were imputed to participants, using postal codes to match geographic areas of residence with Canadian census data.[27,28] Nutritional risk screening was performed on a graded 13-point scale tool.[29-32] Body weight was self-reported and height was measured using standard techniques. Gait, balance, and mobility performance were assessed by the Berg scale[33-36] on a 56-point scale, and by the Timed Up & Go test[37,38] which measures the overall time, in seconds, to complete a series of functional tasks. Subjects' homes were assessed for 37 potential environmental hazards using the Gill's room-by-room assessment form[39,40] Housing types included: single-family house; apartment; row housing or other unique entrance dwelling units; private residential facilities for seniors; other housing, including room in shared accommodation. Data about the use of benzodiazepines (yes/no) and number of daily consumed prescribed drugs were recorded directly from the containers. A detailed history of alcohol consumption was obtained through a questionnaire developed by the Québec Institute of Statistics.[41,42] Responses were categorized for both drinking in the preceding week

(yes/no) and usual drinking during the last 6 months (non-drinker, ≤ 2 times a month, 1-6 times a week, every day). Generally, higher values of the measurements denoted higher risk or impairment, except for the Berg scale where the opposite was true.

Statistical analyses

Descriptive analyses were carried out using SPSS® 13.0; regression analyses using SAS® 9.1. The adjusted effects of subject characteristics on the likelihood of falling were investigated using three survival-analysis techniques (conventional Cox regression, AG extension, and WLW extension), a negative binomial regression, and a logistic regression.[15,43]

The dependent variable in all survival analyses was time to fall for each participant during the follow-up, measured in days. Only cases with at least one month of follow-up fall data were included. Subjects were censored upon reaching 18 months of follow-up (optional voluntary drop out), end of study, or time of withdrawal for any reason. Repeated falls were considered as occurrences of the same type of indistin-guishable events. Survival analyses were performed with all covariates measured on baseline only and with updated covariates. Baseline covariates included age, sex, number of falls in the three months prior to study entry, type of residence, and deprivation index. For the time-varying covariates, including BMI, nutritional risk, alcohol consumption, home environmental hazards, gait and balance, use of benzodiazepines and all medications, the measurement closest to the time preceding the fall was considered.[2] Measurement of exposure to the middle of the follow-up period was used in the case of the people who did not fall. Thus we tested the null hypothesis that the exposure collected during the follow-up was not associated to the risk of falling thereafter.[2] No proportional hazards assumption was required in Cox with time-dependent covariates procedure, since the hazards depended on time.[2,43]

[a] IRR =1.10****; [b] IRR =1.09****.
[c] Subjects monitored less than 12 months who did not declare any falls ($n = 221$) were excluded, given that we could not define the status of faller.
[d] All covariates measured on baseline only; [e] up-dated covariates included home hazards, BMI, Berg and Timed Up & Go scales.
[f] History of falls in 3 months preceding initial interview.

The dependent variable in the logistic regression was the state of being a faller (subjects who fall at least once) over a 12-month period. The negative binomial and logistic regressions were performed with all covariates measured on baseline. The statistical methods are summarized in Figure 1. The linearity assumption of the relationships was checked for continuous predictor variables. All models were fit using a stepwise-like process to retain any variable in the presence of others with a p-value ≤ 0.05. Robust sandwich estimates of variance were used in the survival-analysis, as well as the negative binomial regression techniques, in order to compensate for the lack of independence between multiple falls.

The WLW approach estimated both common and event-specific β for the first five falls of each subject, as well as the common β for all the observed falls. The number of subjects at risk for a given stratum, after the first fall, was made up of all subjects who experienced a fall in the preceding stratum minus those who were lost in the follow-up; n of subjects at risk for a given pooled fall group was made up of all subjects under observation in all considered strata, as if subjects in each stratum represented a different subject. Each model was examined both with and without past fall strata, as it could have masked the effects of other variables of interest.[6,23]

Results

Study subjects

Of the 959 persons who met the study inclusion criteria, agreed to participate, and received a home visit, 22 withdrew without completely filling the baseline assessments or before one month of follow-up. Mean and median follow-up times of the remaining 937 subjects were 488 and 458 days, respectively (range, 27 to 1330 days). Some 549 subjects (57.2%) remained in the study at 12 months and 377 (39.3%) at 18 months. Respondents were mainly women (75.7%). Mean age (standard deviation) was 79.5 (6.7), of which 76.4% were 75 years of age or older. Thirty-nine percent (39.0%) experienced at least one fall in the three months prior to study entry and 14.9% had two or more.

Comparison of statistical methods

Table 1 summarizes the differences in relative risks for falling obtained through several statistical methods. Firstly, the logistic regression (1) and time-to-first fall using a standard Cox (3a) overlooked the recurrence of falls and identified less significant risk factors than did the negative binomial (2), AG (4a), and WLW (5a), that considered all the available information (number between parentheses refers to the concerned model in Table 1). Although both logistic regression and standard Cox identified the same risk factors, logistic regression ignored the time of occurrence of falling. This led to a conclusion of higher magnitude of the related relative risks, compared to standard Cox. The values obtained by the logistic regression were between 17.6% (1.47 vs 1.25) and 39.6% (3.28 vs 2.35) greater than those of standard Cox.

Secondly, three methods - the negative binomial regression (2), the AG (4a), and WLW (5a) extensions of the Cox model considered follow-up time, rate of all falls, as well as dependence between falls, using robust estimates of variance. WLW revealed more significant fall-risk factors than the other methods and accorded less importance to the history of falls in the three months preceding the initial interview. Notably, the negative binomial regression, in relation to the WLW, exhibited a difference of 48.6% (3.15 vs 2.12) for the variable "two or more prior falls". The different emphasis given by these three approaches to the dependence among multiple event times explains the difference in results. The negative binomial regression does not integrate the length of inter-fall intervals. The AG explicitly models the impact of earlier falls on future events. In this regard, the incidence rate ratio (IRR, virtually equivalent to the so-called hazard ratios) of 1.10 of the time-dependent term "number of previous falls" modelled in the AG (4a) indicates a 10% increase in hazard for each unit increase in number of prior falls. In contrast, WLW estimates separate relationships for each fall and computes the coefficients and the within-subject correlation more directly than the AG, thus providing efficient weighted average estimates of effect (and variance).

Thirdly, results were compared for the models both with and without time-dependent covariables. The number of home hazards, an exposure particularly likely to vary during the follow-up, was not significantly associated with falls in any of the models that had only baseline covariates (1 to 5a). On the contrary, the variable was always statistically significant in the same models that controlled variation of exposure throughout time (3b to 5b). All survival models with time-varying covariables identified a greater number of fall-risk factors than did the corresponding technique with only baseline covariates (3b vs 3a, 4b vs 4a, and 5b vs 5a), even when estimates were calculated from the robust variance. A more marked difference was noted between techniques that modeled only time to first fall and those that took into consideration time to each fall. For the marginal WLW model, inattention to time-varying covariables produced bias in various directions. Lastly, results from the usual methods of analysis of risk factors for falling (1 and 3, in Table 1) produced considerable biases relative to the WLW model using time-dependent covariates (5b).

Risk factors for falls

The sample of 937 subjects reported 1,270 falls during a total of 457,283 person-days of observation, given that a same person could report more than one event. Among the subjects, 495 had no falls, 192 experienced one episode, and 250 had more than one. The consideration of the first five falls gathered 90.0% of the 442 fallers and 95.3% of the 937 individuals in the sample. Of all falls for which information on consequences was

available, 44.4% resulted in injuries, 25.2% in activity limitations, 17.1% in a medical consultation, and 5.6% in a hospitalization. Altogether, 82.1% of falls occurred in the subjects' home.

Table 2 displays the adjusted associations between the potential risk factors and the incidence rate for specific and pooled falls. The WLW marginal risk estimates for the first fall stratum in Table 2 are precisely the same as would occur if the analysis were restricted to data on time to first fall using a standard Cox model (column 3b, in Table 1). The only difference is that the *p*-values presented in the former were calculated from the robust rather than standard ("naïve") statistics. However, while the estimates for the first fall stratum are essentially equivalent in these two cases, results for the other strata vary substantially according to whether coefficients are calculated from robust or from naïve methods, providing some indication as to the degree of dependence among the events. Thus, male sex, residential facility for seniors, number of home hazards, Berg balance score, and age significantly and independently predict time-to-first fall. For example, the IRR = 1.45 found for the residential facility for seniors indicated that the subjects living in such places experienced falls at a rate which was 45% higher than for those living in any other kind of housing. Similarly, the IRR of 1.12 for the home hazards indicated a 12% increase in hazard for each unit increase in number of items. However, since age has an IRR of less than 1 (i.e. 0.98), increase in age by one year led to decrease in hazard by 2%.

Table 2 also compares the results when distinct β were fit for each fall. Covariates as age, home hazards, and Berg scale show sustained and relatively constant effects across the strata. Some others differ both in the nature and magnitude of the statistically significant variables, depending on their position in the sequence. The greatest differences in IRR appear in the fifth episode. The entry, in the last step of history of falling in the three months prior to study entry, turned out to be highly significant and did not alter either the magnitude or significance of the IRR for

the other variables already included in all stratum models. The right-hand section of Table 2 repeats the analysis under the constraints of overall common β (weighted average of the event-specific hazards), both when falls beyond the fifth were not applied (censored model) and when all fall data were utilized (complete model). The censored model identified seven variables, three more than the time-to-first-fall model (BMI, use of benzodiazepines, and occasional alcohol consumption in the past six months of follow-up) and one more than the complete model (alcohol consumption). However, these additional variables were no longer significant in the context of the contribution of all others, once the history of falling was joined to the censored model; furthermore, the use of benzodiazepines and alcohol consumption became insignificant in the complete set. An age-sex interaction term tested in each final model was not significant.

Discussion

This article addresses the proper method of examining falls and their determinants. No statistical technique can reproduce human behaviour exactly, and makeshift solutions to time-varying exposures and recurrence of events can lead to severe bias. To our knowledge, the first and only example where time-varying exposures and multiple falls were ascertained simultaneously was in a doctoral thesis deposited in 1991[22] and published later in a scientific review.[23] However, substantial statistical progress has appeared since then. In the current issue, we discuss the various methods for studying the exposure changes during follow-up and recurrent events in the same person. We further illustrate them by identifying the risk factors for falls in the elderly. We have concentrated on the statistical/methodological aspects and have mentioned the risk factor findings only to the extent of showing different results obtained by different analyses.

Methods that handle the aforementioned data analytical features in a statistically correct manner are now available in commercial packages. They have been addressed extensively in the statistical literature, but not yet routinely applied and

reported for fall studies, as new advances in the statistical world are often slow to reach the clinical and public health fields.[4] We have presented throughout our paper our arguments as to why the WLW approach is expected to be an appropriate choice in the context of our study. It provides a natural framework for analysing time-varying exposures and multiple events data using minimal assumptions.[2,44] Other authors have reported that the WLW is robust and performs quite well in many practical situations.[14]

The differences in the estimates obtained through several statistical methods analysing the risk factors for falling, have been illustrated according to the information provided. Results clearly reveal that the usual methods, such as binary outcome using a logistic regression and time to first fall using a standard Cox, produce considerable biases, as opposed to the WLW model that uses time-dependent covariates. In addition, modeling for first events implicitly assumes that the first event is representative of all events. Our study denotes that this assumption is questionable, more in the qualitative facet of IRR estimates than in the quantitative. Our results provide additional evidence regarding the convenient choice of a stratified model rather than a non-stratified one, given that the risk of occurrence varies substantially between occurrences. Mahé and Chevret[45] expect such possibilities when the frequency of events per unit is "small", such as falls among community-dwelling elderly people.

Furthermore, our results are coherent with earlier findings, although we are more confident of the magnitude in estimates of predictors. A few findings merit comment. Number of home hazards and history of falling are strong and consistent predictors of falls, whatever their rank or pooling. Prior overall falls increase the risk of subsequent overall falls. This suggests that if the causes of past falls - for which the variable acts as a proxy - are not corrected, the chances of sustaining further falls due to the same causes are increased.[23] The people living in a residential facility for seniors are more at risk than others to fall, possibly because the variable

acts as a surrogate measure of various chronic conditions and poorer functional autonomy. Similarly, younger people reveal themselves to be at a higher risk of falling compared to the older, probably because of more vigorous lifestyle activities.

We further hope to eliminate any misunderstanding about any incidence measures reported in the research literature, especially the dubious *events per person-time* relating the number of falls (single in some subjects, multiple in others) to the cumulative time of observation of all subjects. It should not be confused with the *individual event rate adjusted for the follow-up time* that we discuss in our paper, or with the *incidence rate* widely used in epidemiology. In the events per person-time measure, the numerator does not express a number of subjects wherein the event only occurs once, but rather a number of events scattered among the study subjects. Windeler and Lange[46] have vigorously denounced this concept because it has no exact interpretation on an individual level. Hence, event rates are the same (20 per 100 person-years) whether 20 subjects are observed for 10 years and each suffers two falls, or 1000 subjects are observed for half a year and 100 (10%) of them have one fall each. Having been introduced in the '80s and still, unfortunately, sometimes reported in peer-reviewed journals[47-50], this concept should be abandoned,[46] as it impedes the search for new approaches.

Happily, prospective design, frequent contacts, repeated measures, and clinical measurements performed by a therapist limited information bias. Nonetheless, some other exposures, such as nutrition screening and alcohol use, were derived from self-reports. Differential misclassification could occur if the fact of a fall or recurrent falls affected the accuracy with which the individuals recalled relevant exposures and subsequent outcomes. This would exaggerate the magnitude of the effect on the risk of falling.[6] Also, the length of time between a fall and the measure of follow-up exposure obviously varied according to the day on which the fall occurred. Hence, an accurate assessment of exactly when a change in exposure to time-dependent covariates might have happened between each six-month follow-up was not possible. It would result in non-differential errors in the measurement of exposures, thereby diluting the observed relation. Another potential for biased results might have occurred because of dropouts, particularly when the latter do not have the same rate of outcome (risk of falling) as those who continue in the study. With the exception of people who refused the services and who were less likely to fall, as opposed to the active participants completing the study, no other reason for loss to follow-up was associated with the falls. Male sex, ageing, residential facility for seniors, first quartile deprivation index, lower Berg score, and daily alcohol consumption at baseline were associated with a significant shorter duration in participation. As Campbell *et al.*[51] have already noted, those individuals who are more frail and may be at greater risk of falling are the ones most difficult to involve and sustain in follow-up. This would also lead to an underestimation of the effects.

All the aforementioned considerations lead us to believe that the results observed in our study tend to be conservative. A practical drawback of the WLW is the pre-processing effort and care required in the dataset construction. The application of this method depends on the completeness of the reports of falls and knowledge of calendar dates of falls. Future research must make the transition from risk factors for falling to community implementation of interventions.

Finally, it would be useful to talk about two substantive clinical findings that have been deleted from the text. Firstly, the degree to which balance and gait mediate the relationship between medication and the likelihood of falling was estimated.[6] A mediator is an intermediate variable that occurs in the causal chain between an exposure and an outcome. If a variable is truly in the causal pathway, the association between the latter two variables should disappear upon adjustment for the mediator.[52] Adjustments for Berg balance scale resulted in a maximum increase of 21% in the effect of benzodiazepines, contrary to the hypothesized reduction. Consequently, the covariate does not act as a mediator or as an appreciable confounder.

Secondly, falls leading to a medical consultation were examined as a secondary outcome, hypothesized as a measure of severity. For these cases, a variable "previous falls" was included as a time-dependent covariate. It was created to consider whether a fall not resulting in a medical consultation had been reported in the three-month period preceding any fall-related medical consultation. Adjusted results identified the number of home hazards (incidence rate ratio = 1.09), the nutrition screening score (1.09), living in a residential facility for seniors (1.67) and fall history (1 prior fall = 0.59; ≥ 2 prior falls = 0.64) as significant and independent predictors for all pooled fall-related medical consultations. Having fallen in the three months before each new event under study was protective against any fall for which people sought medical attention.
